#### **Abstract**

In 1981, Avis and Toussaint gave a linear-time algorithm for the following problem: Given a simple n-vertex polygon P and an edge of P, determine whether each point in P can be seen by some (not necessarily the same) point on the edge. They posed the more general problem of finding a sub-quadratic algorithm for determining whether such an edge exists. In this paper, we present a linear-time algorithm for determining all (if any) such edges of a given simple polygon.

#### I introduction

The notion of visibility underlies many applications, such as image processing, robotic control, computer graphic etc. In this paper, we investigate a question pertaining to visibility in simple polygons. Two points in a polygon are considered (*mutually*) visible if the line segment joining them does not intersect the exterior of the polygon. If a point x is visible from all other points of the polygon P, then x is called a star of P and the set of all stars of P is called the kernel of P; the kernel may be empty. A linear-time algorithm for computing the kernel has long been known [LP79].

In this paper, we are concerned with a more general notion of visibility, introduced by Avis and Toussaint [AT81]: A point of a polygon P is weakly visible from an edge e if there is a point y on e that can see x. An edge e is called a (weak-) visibility edge if e can weakly see the entire polygon. We solve the problem of determining all visibility edges of a given polygon in linear time. Previously, only an  $O(n^2)$  algorithm was known which followed from Avis and Toussaint's linear time test to check whether a given polygon is weakly visible from a given edge.

There are many problems in computational geometry for which linear-time algorithms exist provided that the input polygon is triangulated (e.g. shortest path, visibility [GHLST86], minimum link distance [Su87], polygon separability [ST85]). At present, the best triangulation algorithm for a simple n-vertex polygon runs in

<sup>&</sup>lt;sup>+</sup> This work was done while the second author was with Johns Hopkins University and visited Carleton University.

O(n loglogn) time [TV86]), while a linear-time algorithm is known for triangulating weakly visible polygons [TA82]. The triangulation algorithm for weakly visible polygons requires the knowledge of a least one visibility edge. Our linear-time algorithm detects whether a given simple polygon is weakly visible and reports all visibility edges. Thus the algorithms mentioned above can be speeded up if the polygon turns out to be weakly edge-visible.

The paper is organized as follows, in Section II, we introduce some notation and derive a theorem which, using a recent result of Chazelle and Guibas [CG85], enables us to design an  $O(n \log n)$  algorithm for reporting all visibility edges of a given n-vertex polygon. The remainder of the paper is devoted to improving this bound to O(n). In Section III, we solve this problem for polygons with at least one given visibility edge. We first assume that this edge has two convex endpoints. Subsequently, we show how to drop the latter restriction. In Section IV, we deal with the general case of detecting weak edge-visibility of an arbitrary simple polygon and reporting all visibility edges. The solution is partly a reduction to the previously discussed special cases.

#### II. Preliminaries

Let P be a closed simply connected planar region, whose boundary is given by a polygon of n sides. The boundary of P will be denoted by  $\delta P$ . Let  $\{p_1, p_2, ..., p_n\}$  $p_n$  and  $\{e_1, e_2, ..., e_n\}$ , respectively, be the vertices and the edges of P listed in a counterclockwise order, where  $e_i$  joins  $p_i$  and  $p_{i+1}$ ;  $e_i$  will also denote the vector directed from  $p_i$  to  $p_{i+1}$  and  $e_i^{-1}$  the vector directed from  $p_i$  to  $p_{i-1}$ . Let  $\Lambda(x,y)$  denote the counterclockwise path along  $\delta P$  from the point x to y, where  $x,y \in \delta P$ . A (point, direction)-pair, (x,u), consists of a point x and a direction u such that the ray originating from x in the direction u is locally directed towards the interior of P. Let x be a point on an edge  $e_i$  of P. We define  $\sigma(x,e_i)$  (resp.  $\sigma(x,e_{i}^{-1})$ ) to be  $p_{i+1}$  (resp.  $p_{i-1}$ ) if  $p_{i+1}$  (resp.  $p_{i-1}$ ) is a convex vertex; otherwise,  $\sigma(x,e_i)$  (resp.  $\sigma(x,e_i^{-1})$ ) is defined as the first point on  $\delta P$  hit by the ray from x in the direction  $e_i$  (resp.  $e_i^{-1}$ ). The latter definition is also used to define  $\sigma(x,u)$ , for directions u not co-linear with  $e_i$ . An edge  $e \in \Lambda(x,\sigma(x,u))$  is called a proper edge of  $\Lambda(x,\sigma(x,u))$  if e does not share a point with the ray originating from x in the direction u. Let  $\chi(x,u)$  and  $\chi^{-1}(x,u)$ , respectively, be the set of proper edges in  $\Lambda(x,\sigma(x,u))$  and  $\Lambda(\sigma(x,u),x)$  (see Figure 1). The following fact can be easily established.

**Lemma 1**: The vertex  $p_i$  is invisible from each edge in  $\chi(p_i$ ,  $e_i$ )  $\cup \chi^{-1}(p_i$ ,  $e_i^{-1})$ .

For a point  $z \in P$ , the *visibility polygon* of z, V(z) is the closed set of points in P that are visible from z; if the sides of P are opaque, V(z) is the region of P illuminated by a light source placed at z. An edge on the boundary of V(z) is

called a *window* if it does not belong to  $\delta P$ : Windows of V(z) delimit the illuminated regions from the dark ones in P. Note that if w = ab is a window of V(z) such that a lies in the relative interior of the segment (z,b) (for short denoted by zb) then a is a reflex vertex of P. Any window w partitions P into two polygons one of which contains the point z; we denote the other such sub-polygon by ear(w) of P.

**Lemma 2**: Let  $z \in \delta P$  be a point and let e be an edge of P invisible from z. Then, there exists a vertex  $p_{\alpha} \in P$ ,  $1 \le \alpha \le n$ , such that  $e \in \chi(p_{\alpha}, e_{\alpha}) \cup \chi^{-1}(p_{\alpha}, e_{\alpha}^{-1})$ . Proof Since e is invisible from z, we must have  $e \subseteq P - V(z)$ . Let ear(ab) be the unique ear containing e, where  $a = p_j$  is a reflex vertex of P and lies in the relative interior of the segment zb. In the counterclockwise traversal of V(z) starting from z, if e precedes e then  $e \in \chi(p_{j-1}, e_{j-1})$  and if e precedes e then  $e \in \chi^{-1}(p_{j+1}, e_{j+1})$  (see Figure 2). Clearly, we can choose e to be e to be e to be former and e to be a proof. e to be a proof. e to be a proof. e to be proof. e

The following theorem completely characterizes the edges from which P is weakly visible and also leads to a fast method of identifying them. The proof of this theorem follows rather easily from Lemma 2. First, some more notation is introduced. Let E denote the set of edges of P. Let  $X = \bigcup_{1 \le i \le n} \chi(p_i, e_i)$  and  $X^{-1} = \bigcup_{1 \le i \le n} \chi^{-1}(p_i, e_i^{-1})$ .

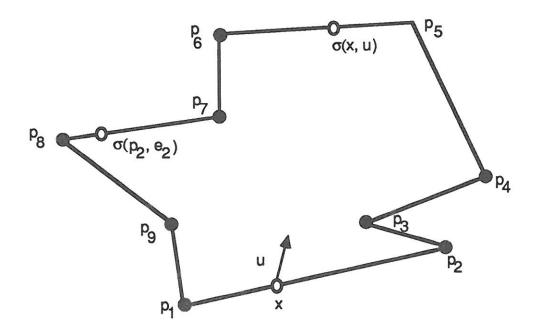

Figure 1: Giving an example for  $\chi(x, u) = \{e_2, e_3, e_4\}, \chi^{-1}(x, u) = \{e_6, e_7, e_8, e_9\}, \chi(p_2, e_2) = \{e_4, e_5, e_6\}, \text{ and } \chi^{-1}(p_2, e_2^{-1}) = \}$ .

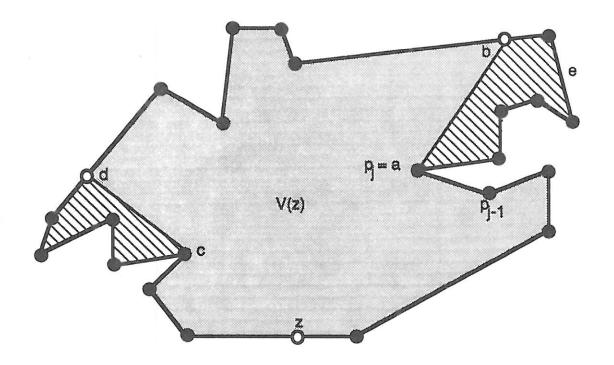

Figure 2: Illustrating the visibility polygon V(z) from a point z and its pockets (shaded).

**Theorem 1:** P is weakly visible from an edge  $e_i$  if and only if  $e_i \in E - X \cup X^{-1}$ . Proof  $\Rightarrow$  Suppose P is weakly visible from an edge  $e_i$ , for  $1 \le i \le n$ . Consider  $p_j \in P$ . Since  $\chi$   $(p_j, e_j) \cup \chi^{-1}(p_j, e_j^{-1})$  consists of only those edges that are invisible from  $p_j$ , and  $e_i$  is visible from  $p_j$  by the hypothesis, we must have  $e_i \notin \chi(p_j, e_j) \cup \chi^{-1}(p_j, e_j^{-1})$ . Since  $p_j$  was chosen arbitrarily, it follows that  $e \notin X \cup X^{-1}$  and the proof is complete in one direction.

 $\Leftarrow$  Let  $e_i \in E - X \cup X^{-1}$  be an edge. We show that P is weakly visible from  $e_i$ . It is known that a simple polygon is weakly visible from an edge if and only if the boundary of the polygon is weakly visible from that edge. Hence, we only have to show that  $\delta P$  is weakly visible from  $e_i$ . Our proof is by *co-linear*. Suppose  $z \in \delta P$  is a point invisible from  $e_i$ . Lemma 2 guarantees the existence of a vertex  $p_\alpha \in P$  such that  $e_i \in \chi(p_\alpha, e_\alpha) \cup \chi^{-1}(p_\alpha, e_\alpha^{-1})$  which contradicts our choice of  $e_i$ .  $\diamond$ 

Using Theorem 1, we can easily design an  $O(n \log n)$  algorithm for computing X and  $X^{-1}$  as follows: Using a result of Chazelle and Guibas [CG85], we can preprocess P in  $O(n \log n)$  to obtain a data structure that computes  $\sigma(p_i, e_i)$  in  $O(\log n)$  time. The indices of the edges of  $\chi(p_i, e_i)$ , for i = 1, 2, ..., n, define a connected interval between 1 and n, where the endpoints of the interval are

computable from  $\sigma(p_i, e_i)$  and  $p_i$  in O(1) time. Hence, X can be computed in O(n logn) time by simply finding the union of all such intervals. Similarly, for  $X^{-1}$ . And thus the set of visibility edges can be determined in O(n logn). In the next section, we present a more complicated O(n) algorithm for computing the weakly visible edge.

#### III Solving the Problem for Edge-Visible Polygons

In this section we show how to compute, in linear time, all visibility edges of a polygon P provided that at least one such edge is known. The discussion restricts itself to computing X since  $X^{-1}$  can be determined similarly. For ease of notation we assume edge  $e_1$  to be the edge from which P is weakly visible. Let us first restrict ourselves to the case where both vertices of edge  $e_1$  are convex; we refer to such polygons as edge-visible polygons with convex base  $e_1$ . Later we show how to overcome this restriction.

To compute X, we linearly scan  $\delta P$ , processing the pairs  $(p_i, e_i)$  in order of increasing i and update X whenever necessary. In the following, all traversals of  $\delta P$  are assumed to be counterclockwise, unless otherwise specified. We call a pair  $(p_i, e_i)$  non-trivial if  $\sigma(p_i, e_i) \neq p_{i+1}$ , otherwise  $(p_i, e_i)$  is trivial. Clearly, whether a pair is trivial can be checked in constant time. During the algorithm, we move a segment  $z_1z_2$  around  $\delta P$  with  $z_1=p_{i-1}$  and  $z_2=\sigma(p_{i-1},e_{i-1})$  or a point co-linear with  $e_{i-1}$  (to be specified later), where  $(p_{i-1}, e_{i-1})$  is the last non-trivial pair processed by the algorithm. At any time during the execution of the algorithm, we maintain that all proper edges of  $\Lambda(z_1,z_2)$  are currently in X. Initially, we set  $z_1 = p_1$ ,  $z_2 = p_2$  and  $X = \emptyset$ . In general, let  $(p_i, e_i)$  be the next (unprocessed) pair considered by the algorithm. If either  $(p_i, e_i)$  is trivial, or  $\sigma(p_i)$  $(e_i)$  lies in  $\Lambda(z_1, z_2)$ , we simply advance to the next pair. Note that, in this case, all proper edges of  $\chi(p_i,e_i)$  must be already in the current X. Otherwise,  $z_1$  and  $z_2$  are advanced on  $\delta P$  and we update X to include all proper edges encountered on the scan from the current position of  $z_2$  to its new position. Our algorithm is described below in pseudo-code.

Algorithm A: Compute X for edge-visible polygons with convex base

input: A simple polygon P known to be weakly visible from the convex base  $e_1$  output: All visibility edges of P

Initialization

 $z_1 := p_1$ ;  $z_2 := p_2$ ;

#### General Step

for i := 2 to n do

If (both endpoints of  $e_i$  are on the closed left half-plane defined by  $z_1$  and  $z_2$ ) or (half-ray( $p_i$ ,  $e_i$ ) intersects the segment( $z_1$ ,  $z_2$ ) at a point other than  $p_i$ ) then

scan the boundary of P starting at  $z_2$  until a point z on the half-ray $(p_i, e_i)$  (but not on  $e_i$ ) is encountered;

place all those proper edges of  $\Lambda$  ( $p_{i+1}$ ,z) into X that have been scanned;  $z_1:=p_i$ ;  $z_2:=z$ 

#### Lemma 3: Let P be an edge-visible polygon with convex base e<sub>1</sub>. Then

- (1)  $\sigma(p_i, e_i)$  equals the first point co-linear with  $e_i$  in a **counterclockwise** traversal of  $\delta P$  starting at  $p_i$ .
- (2)  $\sigma(p_i, e_i^{-1})$  equals the first point co-linear with  $e_i$  in a **clockwise** traversal of  $\delta P$  starting at  $p_i$ .
- *Proof* (1) Suppose that  $\sigma(p_i, e_i)$  is not the first point co-linear with  $e_i$  in a counterclockwise traversal of  $\delta P$  starting at  $p_i$ . Then the open path  $\Lambda(p_i, \sigma(p_i, e_i))$  intersects the ray from  $p_i$  in the direction of  $e_i$  at least twice, thereby creating a region of points which are invisible from  $e_i$ .
- (2) follows analogously. ◊

#### Time Complexity of Algorithm-A

Each execution of the general step considers a previously unprocessed pair  $(p_i, e_i)$  and may also advance  $z_1$  and  $z_2$  on  $\delta P$ . There are only n pairs  $(p_i, e_i)$ . The weak-visibility of P from edge  $e_1$  guarantees that  $e_1$  is not in  $\chi(p_i, e_i)$ , for  $i=1,2,\ldots,n$ , which means that  $z_1$  and  $z_2$  go around  $\delta P$  at most once. Hence Algorithm-A runs in linear time.

#### Correctness of Algorithm-A

Let  $p_i$  be the first non-trivial vertex examined by Algorithm-A. By Lemma 3, the scan-step starts at  $z_2$  (initially equal to  $p_2$ ), and advances counter- clockwise along the boundary of P so as to find correctly  $\sigma(p_i,e_i)$ . All proper edges encountered during that scan are placed correctly onto X (Lemma 1).  $z_1$  are  $z_2$  are assigned to  $p_i$ ,  $\sigma(p_i,e_i)$ , respectively. Thereby P is partitioned into two edge-visible polygons  $P_Z = (z_1,p_{i+1},...,z_2)$  and closure  $(P-P_Z)$  each having a convex base (the convex base of polygon  $P_Z$  is  $z_1z_2$ ). Consider now a non-trivial vertex  $p_i$  in  $P_Z$ . Since P is weakly visible from  $e_1$ , for such a vertex  $p_i$ ,  $\sigma(p_i,e_i)$ 

lies either in  $P_Z$  or on the chain  $\Lambda$  ( $z_2$ ,  $p_1$ ). To ensure linearity of the algorithm repeated boundary scans must be avoided to distinguish between these cases. The algorithm performs an O(1) test checking whether the  $\operatorname{ray}(p_j,e_j)$  intersects  $z_1$   $z_2$ . If the test is false then clearly  $\sigma(p_j,e_j)$  is inside  $P_Z$ . If  $\sigma(p_j,e_j)$  is on the chain  $\Lambda$  ( $z_2$ ,  $p_1$ ) then the subsequent scan of the boundary starting at  $z_2$  correctly identifies  $\sigma(p_j,e_j)$ , i.e.  $z=\sigma(p_j,e_j)$  (by Lemma 3). Otherwise,  $\sigma(p_j,e_j)$  is inside  $P_Z$  and all edges of  $\chi(p_j,e_j)$  are already in X. Algorithm-A, however, continues to scan the boundary of P starting at  $z_2$  until z ( $p_j,e_j$ ) ( $\neq \sigma$  ( $p_j,e_j$ )) is encountered. Since  $z_2$  is initially to the right of the  $\operatorname{ray}(p_j,e_j)$  all proper edges encountered during this scan are on the right half-plane of  $e_j$  and thus cannot see  $p_j$ . By Lemma 2, there exist a vertex  $p_\alpha$  such that these edges are in  $\chi(p_\alpha$ ,  $e_\alpha$ ) which guarantees the correctness of this step. See Figure 3 for an illustration. In general, the segment  $z_1$   $z_2$  may create more than one pocket of P, but since the analysis is similar to the case discussed here it is omitted.

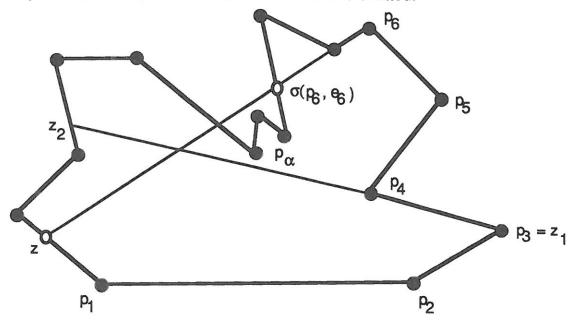

Figure 3: Algorithm-A advances from  $z_2$  to  $z \neq \sigma(p_6, e_6)$ .

**Theorem 2**: Let P be a simple edge-visible polygon with a convex base. Then its set of visibility edges can be determined in time, linear in the number of vertices of P.

*Proof* The visibility edges of P are the edges of E- $(X \cup X^{-1})$ . By the above, Algorithm-A correctly determines X, in linear time;  $X^{-1}$  can be computed in a similar way. The set operations can be performed in linear time.  $\Diamond$ 

Next, we show that Algorithm-A can be modified to report all weak visibility edges for polygons P that are weakly visible from a known edge, say  $e_1$ , whose (one or both) endpoints may be reflex vertices. Without loss of generality, assume both endpoints of  $e_1$  to be reflex. We can partition P into three edge-visible polygons  $P_0$ ,  $P_1$ ,  $P_2$  each of which having a convex base. The main part is then to discuss the interaction of vertices from one polygon and their invisible edges in another polygon. For this, let  $q_S = \sigma(p_2, e_2^{-1})$  and  $q_T = \sigma(p_1, e_1)$ , where  $q_S$  is on  $e_S$  and  $q_T$  is on  $e_T$ . Let  $P_0$ ,  $P_1$ , and  $P_2$  be defined as follows:

$$P_0 = (p_1, p_2, q_r, p_{r+1}, ..., p_s, q_s),$$
  
 $P_1 = (p_1, q_s, p_{s+1}, ..., p_n),$  and  
 $P_2 = (p_2, p_3, ..., p_r, q_r).$ 

Clearly  $P_1$  and  $P_2$  are star-shaped from  $p_1$  and  $p_2$ , respectively. Note that hereby a weakly edge visible polygon P is partitioned into (at most) three edge-visible sub-polygons,  $P_0, P_1$ , and  $P_2$  each of which having a convex base.

**Proposition 1**: All proper edges of  $P_1$ ,  $P_2$  are in  $X \cup X^{-1}$ .

*Proof* The proper edges of  $P_2$ , i.e. all those edges of  $P_2$  which have none of its endpoints in  $P_0$ , are in  $\chi(p_1,e_1)$ . The proper edges of  $P_1$ , i.e. all those edges of  $P_1$  which have none of its endpoints in  $P_0$ , are in  $\chi^{-1}(p_2,e_1^{-1})$ . Thus the result follows.

**Proposition 2**: For all  $p_i$  located on proper edges of  $P_1$ ,  $\sigma(p_i,e_i)$  is in  $P_1$  and for  $p_n$ ,  $\sigma(p_n,e_n)$  is in  $P_0$ .

*Proof*  $P_1$  is star-shaped from  $p_1$  thus  $p_1$  lies on the left half-plane defined by  $(p_i, \sigma(p_i, e_i))$ , for each vertex  $p_i$ , i=s+1,...,n.  $\Diamond$ 

By Proposition 1, we can restrict ourselves to examining those vertices of  $P_1$  and  $P_2$  for which  $\sigma(p_i,e_i)$  is in  $P_0$ . By Proposition 2, this implies that only one of the vertices of  $P_1$ , i.e. the vertex  $p_n$  in  $P_1$  needs to be examined to compute X for  $P_1$ . Analogously for the computation of  $X^{-1}$  for vertices in  $P_2$ . Both computations can be done in linear time; it remains to compute:

- (a)  $X, X^{-1}$  for  $P_0$ ,
- (b) X for all vertices  $p_i$  in  $P_2$  with respect to  $P_2 \cup P_0$ , and
- (c)  $X^{-1}$  for all vertices  $p_i$  in  $P_1$  with respect to  $P_1 \cup P_0$ .

 $P_0$  is an edge-visible polygon with a convex base thus, by Theorem 2, X and  $X^{-1}$  can be computed in linear time (case(a)). The analysis for cases (b) and (c) is quite similar to that of Algorithm-A; it is thus omitted here.

**Theorem 3**: Let P be an n-vertex polygon weakly visible from some known edge. Then all visibility edges of P can be computed in O(n) time. Proof We note that an analogue to Lemma 3 holds for arbitrary edge-visible polygons, i.e. for all  $p_i$  in  $P_2$ ,  $\sigma(p_i,e_i)$  equals the first point co-linear with  $e_i$  in a counterclockwise traversal of  $\delta P$  starting from  $p_i$ . The remainder then follows from Propositions 1 and 2, and the above discussion.  $\Diamond$ 

### IV Computing all visibility edges for an arbitrary simple polygon

To solve the general case of computing all edges from which an arbitrary simple polygon is weakly visible, we partition P into several regions, each of which is weakly visible from some edge. Let  $x = p_X$  be a vertex of P and V(x) the visibility polygon from x with respect to P, constructed in linear time using e.g. [Le83]. Let  $(r_1, \ldots, r_p, l_1, \ldots, l_s)$  be the windows of V(x), where

(a) For i=1,...,p,  $r_i=a_ib_i$  such that  $a_i$  lies in the relative interior of the segment $(x,b_i)$  and cuts off a right pocket,  $R_i=(a_i,...,b_i)$ , whose edges lie to the right of the ray $(x,b_i)$  originating at x through  $b_i$ . For j=1,...,s,  $l_j=c_jd_j$  such that  $c_j$  lies in the relative interior of the segment $(x,d_j)$  and cuts off a left pocket,  $l_j=(d_j,...,c_j)$ , whose edges lie to the left of the ray $(x,d_j)$ .

(b)  $k_1 < k_2$  implies that  $l_{k1}$  precedes  $l_{k2}$  (respectively,  $r_{k1}$  precedes  $r_{k2}$ ) in the

counterclockwise traversal of V(x).

A counterclockwise traversal of V(x) may encounter the windows in order as:

(0)  $r_1,...,r_p,l_1,...,l_s$  (0-switch case)

(1)  $r_1,...,r_{p-1},l_1,r_p,l_2,l_3,...,l_s$  (1-switch case)

The 1-switch case is easier, since, to see both pockets  $R_p$  and  $L_1$ , an edge must extend from the left half-plane defined by segment $(x,d_1)$  to the right half-plane defined by segment $(x,b_p)$ . Additionally, it has to see  $\Lambda(c_1,a_p)$  and the edges containing x. Thus at most three edges are candidates: the edges containing x and the edge containing  $c_1$  and  $a_p$  (if any). In linear time, using the algorithm by Avis and Toussaint, P can be tested for weak visibility from each of these three edges. If the left- and right-window arrangement alternates more than once the algorithm may terminate returning that P is not weakly edge-visible. The edges incident to x are candidates for visibility edges only if at least one of L or R is empty, i.e. left edge at x is a candidate only if L is empty and right edge is a candidate only if R is empty.

We restrict ourselves for the remainder of this paper to the more interesting 0-switch case. We partition P into three polygons  $P_{\text{int}} = (x, b_p, ..., d_1)$ ,  $L = (d_1, ..., x)$ ,

and  $R = (x,...,b_p)$ . See Figure 4. (Strictly speaking, both L and R are themselves composed of two polygons since the boundaries touch at  $c_1$  and  $a_p$ , respectively. For ease of notation this is ignored here.)

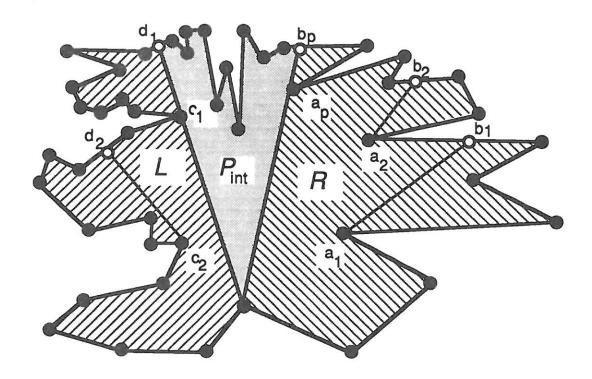

Figure 4: A polygon P and its partitioning into the three polygons  $P_{int}$ , L, R.

**Lemma 4**: Let e(v) denote the edge(s) containing the point (vertex) v. Let  $e_k$  be a visibility edge of P with at most one endpoint in  $P_{int}$ . Then  $e_k \in Q = \{e(c_1), e(d_1), e(x), e(a_p), e(b_p)\}$ .

Proof To weakly see both sub-polygons  $(d_1,...,c_1)$  and  $(c_1,...,x)$  of polygon L, an edge  $e_k$  must lie (at least partially) in the closed right half-plane defined by the ray $(x,d_1)$ . Thus among all edges with at least one endpoint in L only edges  $\{e(c_1), e(d_1), e(x)\}$  are candidates. Analogously for the edges  $e(a_p), e(b_p) \diamond$ 

**Lemma 5**: The polygons  $P_{\text{int}}$ , L, R (defined above) form a partition of P. If  $e_K$  is a visibility edge of P with both endpoints in  $P_{\text{int}}$ , then  $P_{\text{int}}$ , L, R are weakly visible from edges e(x),  $xd_1$ , and  $xb_p$ , respectively. Proof Omitted.

To compute the set of visibility edges,  $W(P) = X \cup X^{-1}$ , for P, we use Lemma 4 and 5, as follows:

Step (1) Choose a vertex x of P and compute V(x)Step (2) If V(x) = P then W(P) can be computed in linear time by Theorem 3

- Step (3) Otherwise, compute the set Q. For each edge e∈ Q test whether P is weakly visible from e using the linear-time algorithm of Avis and Toussaint.
- <u>Step (4)</u> Let  $e \in Q$  be any edge from which P is weakly visible (as obtained from (3)). Using Theorem 3, in linear time, W(P) can be computed and the algorithm terminates.

Otherwise, no edge in Q is a visibility edge for P. Then W(P) consists of only those edges (if any) whose both endpoints are in  $P_{\text{int}}$  (cf Lemma 4) and the necessary condition for weak visibility of P, as obtained from Lemma 5 needs be tested.

- Step (5) Test in linear-time, whether L and R are weakly visible from the segments  $xd_1$ , and  $xb_p$ , respectively. If one of the tests should fail the algorithm terminates and reports that P is not weakly visible.
- Step (6) Otherwise, compute the set of visibility edges  $W(L \cup P_{int})$  and  $W(R \cup P_{int})$  for polygons  $L \cup P_{int}$  and  $R \cup P_{int}$ , respectively. Any edge in both weak-visibility sets is then reported to be in W(P).

As will be shown in the remainder of this section also the final step (6) can be performed in linear time. Since the computations of  $W(L \cup P_{\text{int}})$  and  $W(R \cup P_{\text{int}})$  are symmetric, we discuss w.l.o.g. the problem of determining  $W(L \cup P_{\text{int}})$ .  $W(P_{\text{int}})$  can be determined in linear time (Lemma 5 and Theorem 3). If  $W(P_{\text{int}})$  is empty the algorithm may terminate reporting that P is not weakly visible. Otherwise, consider polygon  $L \cup P_{\text{int}}$ . The set  $W(L \cup P_{\text{int}})$  consists of all those edges in  $W(P_{\text{int}})$  which are not in  $\chi(p_k, e_k) \cup \chi^{-1}(p_k, e_{k^{-1}})$  for any vertices  $p_k$  in L. This is to be computed next.

Let  $p_k$  be a non-trivial vertex in L. Since  $P_{\text{int}}$  as well as L are weakly visible from the segment $(x,d_1)$  we can apply Lemma 3 with respect to polygon  $P_{\text{int}} \cup L$ . We get:

- (a) if  $\sigma(p_k, e_k) \in P_{\text{int}}$  then  $\sigma(p_k, e_k)$  is the first point co-linear with  $e_k$  on a **clockwise** traversal of  $P_{\text{int}} \cup L$  starting at  $p_k$  (or, if wanted starting at  $d_1$ ).
- (b) if  $\sigma(p_K, e_K) \in L$  then  $\sigma(p_K, e_K)$  is the first point co-linear with  $e_K$  on a **counter-clockwise** traversal of  $P_{\text{int}} \cup L$  starting at  $p_K$ .
- (c) if  $\sigma(p_k, e_{k^{-1}}) \in P_{\text{int}}$  then  $\sigma(p_k, e_{k^{-1}})$  is the first point co-linear with  $e_k$  on a **clockwise** traversal of  $P_{\text{int}} \cup L$  starting at  $p_k$ .
- (d) if  $\sigma(p_K,e_K^{-1}) \in L$  then  $\sigma(p_K,e_K^{-1})$  is the first point co-linear with  $e_K$  on a **clockwise** traversal of  $P_{\text{int}} \cup L$  starting at  $p_K$ .

Thus for the computation of  $\cup \chi^{-1}(p_K, e_K^{-1})$  for all vertices  $p_K$  in L (cases (c), (d)), the same analysis as of Algorithm-A holds (running Algorithm-A clockwise), i.e. if

 $z = \sigma(p_k, e_k)$  then the edges reported invisible are correct, otherwise, the false edges reported to be in  $\chi(p_k,e_k)$ , indeed are invisible from another vertex  $p_i$ (Lemma 3).

The more complicated case of computing  $\bigcup \chi(p_k,e_k)$ , for all vertices  $p_k$  in L, is discussed now. The difficulty arises from the fact that to find  $\sigma(p_k, e_k)$  the orientation of the traversal depends on whether  $\sigma(p_k, e_k)$  is in L or not. Testing these for each vertex  $p_K$  may require quadratic time. We can apply Algorithm-A moving counterclockwise around the boundary of  $P_{int} \cup L$  starting at  $d_1$ , with  $z_1=d_1$  and  $z_2=x$ , provided we take an additional step described next.

If point z in Algorithm-A equals  $\sigma(p_k, e_k)$  for all vertices  $p_k$  in L then the result will be correct. Otherwise, the segment  $z_1z_2$  is intersected by  $\delta P$  and our algorithm may fail to report some edges that are actually invisible from  $p_k$ . Let  $X^A$  $(X^{L})$  denote the set of edges of  $P_{int}$  reported by our algorithm as invisible (actually invisible) from the vertices  $p_k$  in L. It is easily seen that  $X^L \supseteq X^A$ . Using Lemma 2, we can prove that all but at most two edges of  $X \stackrel{\mathsf{L}}{-} X ^\mathsf{A}$  belong to  $X(P_{\text{int}}) \cup X^{-1}(P_{\text{int}})$ . Moreover, the missing edges can be found in linear time (e.g. by an additional clockwise scan of the candidate edges of Pint). We use the algorithm of Avis and Toussaint [AT81] from each of these (at most) two edges to see whether P is weakly visible from them. Thus we get:

Theorem 4: Given a simple polygon on n vertices, all the edges, possibly none, from which P is weakly visible can be found in optimal O(n) time and space.
